WONDER BOOKS
NEW YORK
Introduction

The moon has been the subject of speculation and imaginative questioning by mankind through the ages. A close neighbor in space, its rhythmic sequences of color and form are visible even to the least observing. Yet at times everyone observes the moon. Such a glorious neighbor in space must have a special significance! The wonder of it has raised hundreds of questions. And now the answers may be ours. For at long last man is on the threshold of going to the moon.

This How and Why Wonder Book of the Moon prepares the reader to understand the moon explorations. Not only does it summarize much that is already known, it also states clearly some of the major questions yet to be answered. In many ways our attempt to reach the moon illustrates science and technology working hand-in-hand in spectacular ways. At first it seems that only outer space is the laboratory in this exploration. But closer thought reminds us that the results of research of many kinds — from test tubes to mathematics to telescopic probing of the vast universe — have contributed to the soon-to-be accomplished flights to the moon.

Living in the twentieth century is exciting. Think of the opportunities that children at school and whole families at home have to learn about new scientific advances. This How and Why Wonder Book of the Moon takes us to the frontiers of knowledge about our Earth’s major satellite. Surely moon-gazing, always a popular activity, will never be the same again. And in a day when the question is not “Shall we look at the moon?” but “Shall we take a trip to the moon?”; the great yellow sphere emerging in full splendor over the eastern horizon has a new meaning for everyone.

Preface

From the beginning of history, man has been obsessed by the desire to travel to the moon. A seal, carved in Babylon 3,000 years ago, shows a man mounted on the back of a large bird obviously headed for a tiny crescent moon that shows in a corner of the seal.

This is the story of the approaching realization of this age-old dream. Project Apollo is the plan which will one day place a man from earth on the desolation of the moon. What we now know about the moon and what more we must learn about it before we can risk human lives on this exploit are told here. Here also is the story of the carefully detailed preliminary research — the manned and unmanned explorations that must precede the actual event.

This may be man’s greatest adventure. It will be one upon which he will embark with his eyes open, not blindly or desperately, as he has on many past explorations. The story of Project Apollo is as exciting as must have been the preliminaries for the voyages of Columbus, about 1490.

James S. Pickering
Hayden Planetarium
For the first time in all history, man is reaching out to probe the mysteries of space. Scientists have already sent our astronauts more than 150 miles high, hurtling in orbit around the earth at speeds of over 17,000 miles per hour.

Before you are much older, the first human explorers will set foot on the moon. From there, the next stepping stone in the conquest of space will be Mars, and after that the other planets. Then, at some unforeseeable date in the future, man plans to go on to the distant stars themselves.

Since the moon is the closest of all the heavenly bodies, it will be the first to be probed by men from earth. In this book, we will seek some answers to questions about what the moon is like; what our astronauts are likely to find when they get there; and how they will make the long and hazardous voyage through the empty reaches of space.

There have been a great many scientific theories about the origin of the moon. Of these, only the three most likely will be discussed here. The first holds that the moon is a thrown-off portion of the earth itself. When the earth was new...
and in a semi-liquid form, its rapid revolution around the sun caused it to assume the shape of a lop-sided dumbbell. The smaller part of the dumbbell broke away and became the moon.

A corollary to this theory is that after the earth had begun to solidify, a huge chunk of it was torn loose from what is now the basin of the Pacific Ocean. About the only justification for this latter theory, most scientists think, is the fact that the total mass of the moon would just about fill the hole that is now filled by the Pacific’s waters.

Other scientists believe that the moon is actually older than the earth. They contend that the moon is a relic of an earlier stage of the solar system than that during which the earth was formed. Toward the end of the earth’s forma-

Most scientists today accept the theory that our solar system was formed from a cosmic cloud.

The sun forms.

The planets and moons form within the dust rings.

Moons are captured by the planets’ gravitational pull.
tion, it caught the moon in the force of its gravity and captured the moon as a permanent satellite.

Most scientists today, however, accept the theory that the moon and the earth were formed at the same time and of the same basic materials. They think that several billion years ago our solar system was nothing but a cloud of cold dust particles whirling aimlessly through the nothingness of deep space. Then, in response to the laws of gravity, these particles gradually came together to form a huge, spinning disk. As it spun, the disk separated into rings. The nucleus of the disk became the sun, and the particles in the outer rings became the planets. When both earth and moon had been formed, the moon, being much the smaller, was captured by the stronger gravity of the earth and began to orbit about it just as the earth orbits around the sun. (See ill. p. 5.)

Because the moon is the nearest heavenly body to the earth, and because it appears at different times of the month in several varied forms, a great many myths and superstitions have grown up about it. Here are a few of the most common.

Many people believe that the moon affects the weather. When the moon changes, they say, the weather changes. As a result we get-old-time sayings that have been handed down from generation to generation:

“Clear moon, frost soon.”

“Pale moon means rain. Dark moon means winds.”

“When the moon can be seen in the daytime, the days are cool.”

“Frost in the dark of the moon kills buds and blossoms; frost in the light of the moon does not.”

Anyone who stops to think about it soon realizes that the moon cannot possibly change the weather on earth. First, it is an inert body, a quarter million miles away, which transmits no energy except a weak reflection of the sun. In the second place, the moon can be seen over half the earth at the same time, in the tropics as well as the arctic, and obviously every place on earth does not have the same weather.

Many old-timers also believe that the moon affects the growth of seeds and plants.

“Plant beans when the moon is light.”

“Plant potatoes when the moon is dark.”

“Wood keeps better when cut in the new moon.”

“Trees should only be pruned in the new moon.”

For centuries farmers have planted and tilled their crops in accordance with these ancient rules. But no one has ever been able to prove that the moon has anything at all to do with earthly harvests.

Since long before the first history books were written, people believed that the full moon caused insanity. In fact, the word “lunacy” comes from the Latin word “luna” meaning moon. It was believed that if the full moon shone on a person while he were sleeping, that person would go mad. Another old superstition said that moonlight could cause blindness. But since moonlight is nothing more than reflected sunlight, the sun should cause a great deal more madness and blindness than the moon.
The moon has always figured prominently in both ancient and modern religion. It was worshipped as a goddess by the Greeks and Romans, as well as native tribes in Asia, Africa, Australia, and North and South America.

Today, the phases of the moon play an important part in the celebration of both Christian and Jewish Holy Days. The Christian festival of Easter always takes place on the first Sunday after the first full moon after the vernal equinox. One of the most sacred of all days in the Jewish faith, Passover, always falls on the first full moon of the spring, from the 14th to the 21st day of the Hebrew month Nisan.

The full moon which is nearest in date to the autumnal equinox (September 23) is known as the “harvest moon.” At this time, the moon rises early in the evening for three nights in succession, and is entirely or nearly full on each of the nights. Thus the light of the moon lengthens the natural period of twilight, and allows farmers extra hours of working time in which to harvest their crops before the fall frosts set in.

The “hunter’s moon” follows the harvest moon, one month later, and is very similar to it. It is so called because the hunting season follows the gathering in of the crops.

There have been many fantastic tales told about the moon. But perhaps the most ridiculous was the “great moon hoax” of 1834. The amazing thing was that most of the people of the world, including a great many leading scientists, were completely taken in by it.

It all began one afternoon when a reporter for the New York Sun, Richard Adams Locke, was trying to think of a
sensational story to write for his paper. It had been a dull day for news. Nothing of much importance was happening in the city. So Locke let his imagination take over.

He knew that Sir John Herschel, the famous British astronomer, was making moon observations at that time from the Cape of Good Hope in Africa. That was enough of a start for the imaginative Mr. Locke. His story took it from there.

He reported that Sir John had developed a telescope twenty-four feet in diameter, which was big enough to bring the moon into view at a relative distance of 150 yards. Through it, the astronomer could see flowers, white beaches, and a huge jewel-like rock, probably a ruby, that was 90 feet high. In a valley nearby, so went Locke's fanciful story, were herds of small bison and blue unicorns, as well as flocks of pelicans and other birds.

As the days went past, Locke's news stories grew even more fantastic. He reported the finding of two-legged beavers, horned bears, and human-like creatures that were half-man and half-bat.

After a few weeks of writing this fabulous hoax, Locke decided to quit. But by this time, the circulation of The Sun, which had been a small, unsuccessful paper, had ballooned into the largest in the city. Locke himself became famous, even after he had confessed that his stories were only wild figments of his imagination.

If you wonder about the relation of size between moon and sun, you might understand it better if you realize that the sun is much larger than the earth-moon system together.

The moon is "only" 6,800 miles in circumference and 2,160 miles in diameter. This means that a line drawn through its axis would extend "only" from New York to Salt Lake City.
The visible side of the moon. More than 30,000 craters are mapped, ranging in width from the largest, Baily, 183 miles in diameter, and Clavius, 146 miles, to the smallest photographed, ¼ mile in diameter. The deepest crater is Newton, 29,000 feet. The highest mountains, Leibnitz and Doerfel exceed 30,000 feet and are thus higher than the highest mountain (Everest) on earth. The largest visible valleys are Rheiota Valley, 115 x 15 miles, and Alpine Gorge. The largest seas are Mare Imbrium (Sea of Showers), which covers about 340,000 square miles and Oceanus Procellarum (Ocean of Storms).

The principal features of the moon's surface are its mountain ranges, its craters, and its seas. Almost all of them have been given names for identification.

The sea areas, first observed by the earliest astronomers like Galileo were given Latin names: Oceanus Procellarum (Ocean of Storms), Mare Imbrium (Sea of Rains), Mare Humorum (Sea of Moisture), Mare Nubium (Sea
of Clouds), *Mare Vaporum* (Sea of Vapors), *Mare Tranquillitatis* (Sea of Tranquillity), *Mare Focunditatis* (Sea of Fertility), *Lacus Somniorum* (Sea of Dreams), and many others.

For the most part, the important mountain ranges were named for mountains on earth: Alps, Apennines, Caucasus, Jura, Carpathian, Pyrenees. Others, such as Leibnitz and Doerfel, were named for famous astronomers.

The craters also took their names from great scientists and philosophers, both ancient and modern: Plato, Copernicus, Euclid, Archimedes, Faraday, Cavendish, Ross, Pickering, Lee, Newton, and scores of others.

When the Russians made the first charts of the moon's "far side," they named the outstanding new features which they discovered: Moscow Sea, Soviet Mountains, and Tsiolkovsky, Lomonosov, and Tsu Chung-Chin craters.

The mountains on the moon were probably formed when the moon was in the process of changing from a liquid to a solid and its interior was molten. As it cooled, the surface wrinkled and cracked like a dried-up skin of a prune. It was in this same way that the mountains on earth were originally created.

At one point, the Leibnitz Mountains tower 29,000 feet above their base. This is as high as Mt. Everest, the tallest mountain on earth. Recent calculations, which have yet to be confirmed, indicate that some moon mountains may exist which are even higher.

Altogether, some 30,000 craters have been counted on the moon. These range in size from the crater with a diameter of as much as 150 miles from rim to rim, to comparatively small pock-marks less than half a mile in diameter. The crater, Clavius, for example, is about 146 miles in diameter. If you were standing in its center, its rims would be invisible, completely hidden from view beyond the short lunar horizon.

Scientists have no way of knowing exactly how these craters were created. It is believed however that some of the smaller ones may have been the result of volcanic activity during the moon's formative stages. Indeed, a few years ago, one astronomer observed what he
believed to be an outburst of gas from the inside of the crater Alphonsus. If this observation was correct, it would indicate that the interior of the moon is still hot and gaseous, and that a possibility of volcanic activity on its surface still exists.

Since only a few lunar craters resemble earth volcanic-craters, it is supposed that most of them were caused by the tremendous impact of large meteors striking from outer space. Some scientists believe that a meteor hitting the surface of the moon at an angle would make an elliptical crater that becomes round due to the heat of impact. Other scientists argue that whatever the angle of impact, the crater would be round. The craters on the moon are mostly round.

The size of the meteors that created the larger craters must have been enormous, triggering explosions many thousands of times greater than the most powerful nuclear bomb. The moon is constantly being bombarded by meteors, both large and small.

The earth, too, is under a constant meteor bombardment. But when a meteor approaches earth, it is burned up and vaporized as it comes into contact with the heavy layers of atmosphere. The larger ones we see as “shooting stars.” Sometimes, if the meteor is originally large enough, a small core of it survives and lands on earth as a chunk of metal.
But since the moon has no atmosphere, a meteor can strike it with full force, and thus gouge out a big depression on the surface.

The winds and waters of earth are constantly at work to change the earth's surface and erase the marks of its geologic history. But the moon is without the erosive effects of wind and water. Thus, it is almost certain that every scar inflicted on the moon’s surface in the past two or three billion years remains exactly as it was when it was first made.

Scientists have not observed any new craters of appreciable size that have been created on the moon since the invention of the telescope. From this we might conclude that the meteoric bombardment of the moon — especially by giant meteors — has not been as great in the last few hundred or few thousand years as it was in the distant past.

Rills are less prominent features of the lunar surface. They are cracks in the rock, some shallow and some deep, extending in length from one or two miles to several hundred. These cracks were probably created when the surface of the moon cooled.

We know very little about the rills because, compared to the mountains and craters, they are too small to furnish much accurate data for our earth cameras to record in detail. We know that they exist, and that is about all we do know about them.

One of the most puzzling mysteries of the moonscape are the rays. These are bright streaks that fan out in all directions from some of the bigger craters, notably Tycho, Copernicus and Kepler, and from many of the smaller ones as well. Some of these rays emanating from Tycho are so long that they extend more than 2,000 miles from the crater and disappear over the horizon into the moon’s far side.

No one has ever been able to determine just how these rays were originally formed, or what they consist of. The most popular theory is that they are long streamers of moon dust that were scattered by the meteors that formed the craters.

You can see how this might have happened if you place a small pile of fine face powder on a piece of dark paper and then strike it sharply with
The seas, like the Mare Imbrium shown here, have no water. At top left, are the Apennine Mountains.

the round side of a spoon. The powder will fly out in all directions in precisely the same pattern as that of the rays we can see on the moon.

Since there is no air or wind on the moon to disturb these dust patterns, they would have remained exactly as they were when they were originally made.

Another theory holds that the rays may be composed of a lighter-colored sublunar material that was blasted from the crater by the meteor. The heat of the meteor's impact and explosion may have melted and fused this material into a glass-like form. Such glass particles would reflect light, and thus might account for the fact that rays vary in brightness as phases of moon change.

The great level plain areas of the moon are called "seas." The earliest astronomers, gazing at the moon with their primitive telescopes, did not
know that the moon was a lifeless, waterless body, and reasoned that parts of its surface must be covered by water like the seas on earth. We know now that the "seas" are dust-covered deserts, but they have been allowed to keep their original designations as "seas." And indeed at one time, when the moon was being formed, they were probably actual seas of molten lava.

Since the "seas" are flat and apparently less hostile than the more rugged mountain areas of the moonscape, it is here that the first spaceships from earth, both unmanned and manned, are expected to make their initial landings.

Earth telescopes, as we have seen, can provide us with fairly accurate details of the larger features of the moon's surface. But since telescopic lenses cannot clearly focus on any object less than half-a-mile long, we do not know for certain what the surface is like. Much of our knowledge of the close-up details of the lunar surface depends upon the analysis of radar echoes and reflected sunlight. A large part is also educated guesswork, based on reasoning and logical surmise. For this reason, many astronomers differ widely as to their opinion of the precise details.

All scientists are in agreement that the moon is covered by a layer of dust, created by the impact of meteorites and by the disintegration of the moon-rock. This disintegration results from the violent and extreme changes in temperature. The earth's surface rocks crumble into dust due to the same causes.

Some believe that the dust layer is only a few inches to a few feet deep. Others hold that it may be several hundred feet deep. The general consensus is that the thickness of the dust layer varies; it is probably very deep inside the craters, but relatively thin on the broad flat areas of the "seas."

When the first Russian moon-shot crashed on the lunar surface a few years ago, one Soviet scientist reported that it kicked up a shower of dust that arose to a height of nearly 500 miles before settling back. If this is true, it would indicate that the depth of the dust cover is considerable.

A very thick layer of dust would be
a terrible hazard to the first manned spaceship. Upon landing, its retro-rockets could blow a hole in the dust layer that would completely bury the ship and its occupants. One of the essential jobs of the unmanned moonships will be to determine exactly the thickness of the moon's dust cover.

There are many other scientific theories about the make-up of the moon's surface. It has been suggested that the radiation from the sun has hardened the upper layers of dust into a crust on which a spaceship could land and explorers could walk. Another theory states that ceaseless solar radiation over a period of billions of years has turned the moon's dust into a sort of frozen foam into which a ship or a man would sink to frightful depths.

One scientist has advanced the theory that the moon may be covered, at least in part, with thin, bristle-like stalagmites of hardened lava known as Pele's hair. These are often found after the eruption of volcanoes in Hawaii. On earth, wind erosion makes short work of such stalagmites. But on the moon, with no wind to affect them, they would be permanent fixtures.

One of the tasks of the first unmanned moon rockets will be to get as many answers as possible to the question of what the moon's surface is really like.
If we accept the most popular scientific theory, namely that the moon and earth were formed at the same time and of the same basic material, then we can theorize that they probably followed the same basic pattern of evolution. In this case, the moon once had an atmosphere, and also a form of water.

Why, then, if this atmosphere and water remained on the earth, did it not also remain on the moon? Most scientists believe that the answer lies in the difference between the force of the earth’s gravity and that of the moon’s.

The pull of the earth’s gravity keeps our atmosphere and water from escaping into space as the earth rotates. But the moon’s gravitational pull was not strong enough to hold onto its own atmosphere. Therefore, over millions of years, its air and moisture escaped into the void of space.

There is, however, a trace of atmosphere on the moon: a few gaseous molecules that cling to cracks in the surface. At the most generous estimate, this atmosphere amounts to no more than one-millionth that of the atmosphere on the earth’s surface. This would roughly be equal to the air pressure that exists 70 miles above the earth. So, for all practical purposes, we may assume that the moon is a cold, lightless, airless, waterless globe.

Moon explorers, then, will have to wear clothing that not only provides them with an oxygen supply, but which also protects them from the total lack of air pressure as well as the extremes of heat and cold.

Since the moon is airless and waterless, it is generally supposed that it is also entirely lifeless. However, as in most things concerning the moon, there have been differences of opinion.

Some scientists have proposed that the changes in color that occur in certain moon craters may be due to a species of vegetation that grows there during the hot moon-day. Presumably, if such vegetation exists, it freezes up during the cold moon-night, and then comes back to life when the sun shines again. This cycle would be comparable to that of trees on earth, which appear lifeless during the winter, and leaf and blossom again in the spring.

One astronomer observed moving patches on at least one of the crater floors. He reasoned that these might be swarms of some kind of insects, feeding on the vegetation. Most authorities, however, agree that any sort of life on the moon as we know it is impossible.
There are 31 moons in our solar system. Earth, Mars, Jupiter, Saturn, Uranus and Neptune all have satellites. Of Jupiter’s 12 moons, only 4 are named; the other 8 are very faint. The satellites of the other planets are very tiny and, it is theorized, may be captured asteroids.

Nonetheless, one of the first tasks of lunar explorers will be to bring back samples of moon “soil” to be tested for any form of life that we could not observe with a telescope.

As far as we know, there are thirty moons, other than our own, revolving around the other eight planets in our Solar System. Mars has 2; Jupiter 12; Saturn 9; Uranus 5; and Neptune 2.

Strictly speaking, these satellites should not be called moons, since the only true moon is our earth satellite. But because they are usually referred to as “moons,” that is what we will call them here.

The two moons of Mars, the planet most similar to earth, have been named Deimos and Phobos. Both are very tiny: Deimos is only five to ten miles in diameter and Phobos is about twice that size.

We know that the “escape velocity” from earth — the speed necessary for a space vehicle to fling itself loose from
the earth’s field of gravity — is about 25,000 mph. Only the most powerful rockets in our NASA supply are capable of such a tremendous thrust. But the gravity on Deimos is so weak that a man could jump clear off the tiny moon, hurling himself into space by the power of his leg muscles alone. Any future astronaut who might happen to land on Deimos, will have to be very careful, or he may find himself floating free in outer space.

Because these moons of Mars are so small, a curious theory has been advanced to account for them. Mars appears to be a dying planet, and some people think it once had an atmosphere like ours and was populated by intelligent beings. When the atmosphere thinned out, making life on the planet impossible (so the theory goes), the Mars-men built two giant spaceships in which they could continue to live under artificial conditions, and put them into orbit. These man-made moons are Deimos and Phobos — if the fantastic theory is true.

Galileo, as we have learned, discovered the four largest moons of Jupiter. These have been named Io, Europa, Ganymede, and Callisto. Io is about the size of our moon; Europa is slightly smaller, and the other two are slightly larger. The first three seem to be made of rock, like our moon, but it is possible that Callisto may be a solid ball of ice, or perhaps a rock core covered with ice.

During recent years, astronomers have detected eight more moons orbiting around Jupiter. All of them are small, ranging in size from 20 to 150 miles in diameter.

Saturn has nine known moons. The largest one, Titan, is the biggest moon in our solar system. It is about the size of Mars, and appears to have an atmosphere of its own, probably composed of methane gas. It is believed that some of Saturn’s smaller moons may be, like Callisto, nothing but balls of ice.

In addition to its nine moons, Saturn also is surrounded by a spectacular ring. This ring is composed of billions of tiny moons, ranging in size from specks of dust to baseballs. Since the rings are good reflectors of light, it is thought that they too are tiny ice balls or ice-covered rocks.

We know very little about the moons of Uranus and Neptune, except for the fact that Uranus has five and Neptune two. The smaller of Neptune’s moons, Neiréd, is only about 200 miles in diameter. The larger, Triton, is a giant, its diameter being between 3,000 and 5,800 miles.

But of all the moons in the sky, the one that interests us most is our own.

If we accept the theory that the moon was formed from the same basic materials as the earth, then we may assume that it contains much of the same elements that are found on earth: iron, aluminum, lead, nickel, nitrogen, hydrogen, etc. One of the main reasons for sending manned spacecraft to the moon will be to determine exactly what kinds of metals and minerals do exist there; in what quantities they are to be found; and what is the best way to mine them.

The metal deposits of the earth are
gradually diminishing, although it will probably be thousands of years before they are completely exhausted. But scientists look to the deposits on the moon to provide raw materials for earth's industries well into the distant future.

One leading authority has suggested that large deposits of ice and water may lie only a few dozen, or a few hundred, feet beneath the lunar surface. If this is so, these deposits can furnish supplies of water for moon explorers to drink — and, by the relatively simple process of electrolysis (the chemical breakdown of water into its component parts of hydrogen and oxygen), supplies of oxygen for them to breathe.

For many centuries man has dreamed a wistful dream of someday going to the moon. But it was not until the past few years that modern developments in rocket engines have made such an attempt feasible. The United States National Aeronautics and Space Agency (NASA), and the Russian space agency, are already planning for the great adventure.

Many people have asked: "Why is it worth spending billions of dollars to land teams of explorers on the moon?" There are a number of reasons.

While astronomers already know a great deal about the surface of the moon, there is much that telescopes and radar beams cannot disclose. Is the dust
cover thin or thick? Is there a crust? Is the surface foamy? What kind of rocks, ores, and other minerals and elements does the moon contain? What is the “soil” of the moon like? Does it contain dormant life? What is the exact effect of solar radiation upon the lunar surface? Does the moon contain sub-surface ice and water?

Is it safe for human beings to fly through belts of radiation that may be deadly? Can spaceships travel through clouds of meteorites and other cosmic debris that whizz through space at velocities of up to 25,000 miles per hour?

Normally, the instruments of unmanned spacecraft can discover the answers to such questions as these more reliably than a man. But a machine can only do what it has been built to do. It cannot cope with the unexpected. Only man can handle the unforeseen. That is one reason why scientists feel that man must go to the moon.

The surface of the earth lies at the bottom of a deep, heavy sea of atmosphere. Through even the finest, most powerful telescopes that man has been able to produce, the pictures of the stars — and even of the moon itself — are more or less distorted.

The moon’s almost total lack of atmosphere, and thus of atmospheric distortions, make it the ideal location for an astronomical observatory. Astronomers say that a relatively small 20-inch telescope on the moon would accomplish as much in probing the mysteries of outer space as the giant 200-inch telescope at Mount Palomar, the world’s largest. And if a 200-inch telescope could be placed in an observatory on the moon, the possibility of further discoveries would be endless.

It has been pointed out that the moon’s surface, and every geological moon-mark upon it, has in all likelihood remained unchanged for billions of years. There has been no wind, no erosion, no weather to change them, as has been the case on earth. Therefore scientists are hopeful that this changeless record of the moon’s history may go far to answer many of the puzzling riddles about the origin and development of the solar system as a whole.

With its low gravity and absence of atmosphere, the moon would be an almost perfect way-station from which to launch spaceships to the other planets. Less than one-sixth of the escape velocity would be required to lift a vehicle off the moon than would be needed to lift it off a launching pad on earth. This tremendous difference in pay-load would allow the ship to carry infinitely much more fuel for maneuvering once it was in space.

Already, our space scientists are looking forward to the day when the moon will become the earth’s great spaceport.

As mentioned earlier, mineralogists believe that the ores and metals which are almost sure to be found on the moon

Artist’s conception of a moon-city. Fantastic? Yes. But less so than Jules Verne’s novel in 1874 “From the Earth to the Moon.” One of the illustrations of the novel showed the moonship after landing, and the passengers observing the Universe (inset above).
can provide a nearly limitless source of raw materials for earth’s industries. Once permanent landings have been made on the moon, methods of mining and transporting these minerals should quickly follow.

Finally, it has always been the nature of man to want to explore the unknown. Because of this urge, the early sea-farers found the New World; American pioneers discovered and developed the great country that lay over the western mountains; Arctic adventurers opened both the north and south polar areas to exploration.

A famous mountain climber was once asked why he wanted to scale the dangerous heights of Mount Everest. He replied simply: “Because it is there.” That is undoubtedly one of the reasons why men want to land on the moon. Just because it is there.

These are the missiles that are used to prepare the research and will be used to attempt the moon landing. From left to right: The Atlas used in Project Mercury, which sent our astronauts into orbit around the earth; the Titan, used in Project Gemini, which will perfect the techniques of meeting with tankers while in orbit; the Saturn C-1, used to test Apollo components and the Advanced Saturn, which will be used for Project Apollo, the manned landing on the moon. The missiles are compared in size with the Washington Monument in Washington, D.C., towering 555 feet. The Advanced Saturn will be about 350 feet high, higher than the Statue of Liberty in New York Harbor.

It is inevitable that the first crew of spacemen that lands on the moon will be likened to Christopher Columbus. And in many respects this will be true. They will have pioneered the way across a dangerous and forbidding sea — in this case the sea of space — and will have set foot upon a hostile soil that no man has ever seen before.

But whereas Columbus could only guess at what he would find, the pioneer spacemen will have a good idea of what to expect. In 1492, most men believed that the earth was flat, and that if a ship sailed to its edge, it would plunge off into some fearful, bottomless abyss and be lost forever. They also thought that the sea was guarded by fierce monsters that could swallow a ship and its crew at one gulp. Columbus did not believe these fanciful tales, but he had to risk his own life and the lives of his crew to prove that he was right.
The unknown into which our space-men will venture will present dangers much more real than those which Columbus faced. Even with as much knowledge as we already have about the moon, we still cannot be sure that a spaceship, making its first lunar landing, will not sink hundreds of feet into a quicksand of loose dust or frozen foam. We do not know the extent or deadly effects of solar radiation on the moon’s surface. The answers to these and dozens of other questions just as vital can mean the difference between life and death to our moon pioneers. But whereas Columbus had to find out all the answers for himself, the National Aeronautics and Space Administration is planning to send out a series of robot spacemen, unmanned vehicles that are crammed with scientific instruments, to eliminate as much of the guesswork and danger as possible before the first men try for a landing. Already, the value of first sending *unmanned* craft to the moon has been amply demonstrated. Two such vehicles, aimed at a crash landing on the moon, have thus far failed. The first one missed the moon by about 22,000 miles and went into permanent orbit around the sun. The second lost its power. In both cases, had they been manned by human crews, the crews surely would have been lost.

The first unmanned moon probes planned by NASA are known as Rangers. According to present plans, there will be several types of
Ranger, the space robot, on its way to the moon to assemble information necessary for the men who will follow later.

The instrument package, already separated from its carrier, is slowed down by a retrorocket to soften the impact of the crash.

The balsa ball, flattened by impact (instrument package exposed in cutaway illustration), comes to rest on the surface of the moon.
vehicles in this class. It is very likely that the first one will have made a moon landing before you read these words.

The Ranger will be a small but complicated vehicle. In one section it will carry a television camera, and instruments to detect radiation and other lunar phenomena. It will also carry an instrumented capsule that will actually make a safe moon landing. Ranger will work like this:

After being lifted off its launching pad at Cape Canaveral by a giant Atlas rocket, it will be hurled into an earth orbit by a booster rocket at a speed of 12,600 MPH. Halfway around the world, at a point above South Africa, a second blast from the booster will thrust it into a moon trajectory. At this point its speed will have increased to 24,500 MPH, sufficient to allow it to escape from an earth orbit and head out into empty space. At this point, the booster rocket will drop off, and Ranger will be on its own.

Now the amazingly intricate instruments will begin to unfold. Wing-like panels will spring out from its sides. These panels will capture energy from the sun to be turned into electricity to power the Ranger's TV and radio equipment. With the radio working, Ranger will be able to be controlled from ground stations on earth. By the aid of small guidance rockets, the robot will be put on a precise course for a moon landing.

As it approaches the moon's surface, some 66 hours after launching, TV cameras will begin taking the first close-up pictures of the moon. While scientists using earth-bound telescopes cannot see moon-objects less than half-a-mile long, Ranger's camera will be able to record objects no larger than a dining-room table. The pictures will be radioed to earth as rapidly as they are taken, and for the first time scientists will know what the lunar surface looks like in minute detail.

Now the most amazing part of the...
MPH; and this speed will be increasing every second due to the pull of the moon's gravity.

When the Ranger is some 70,000 feet above the moon, a retrorocket will blast the balsa ball away from the main body. The retarding force of this little rocket will bring the ball to a momentary stop at a moon-altitude of about 1,000 feet. Then the rocket will jettison itself and the ball will fall free to the surface below.

Meanwhile, the cameras on Ranger will continue to take close-up pictures of the moon and relay them back to earth until Ranger strikes the rocky surface and is completely disintegrated upon impact.

Beginning its fall all over again, from its temporary stop at 1,000 feet, the ball will strike the moon's surface with a speed of no more than 150 MPH. Since the ball was built to withstand this much of a jar (this has been proved by dropping it from airplanes), it will probably bounce once or twice and then roll to a stop — the first man-made object ever to land safely on the moon!

The ball itself is made of segments of balsa, the lightest and most resilient of all woods, which are fitted together in such a way as to be best able to absorb the jolt of landing. Its peculiar paint pattern is designed to reflect and absorb lunar sunlight, and thus help offset the moon's extremes of heat and cold.

Inside the ball is a seismometer, an earthquake (or in this case a moonquake) recorder, and a radio transmitter. This seismometer can show us many things about the mysteries of the moon.
For one thing, it can record the number of meteorites that strike the moon, as well as their size, and radio its findings back to earth. This information could mean the difference between life and death for the first moon pioneers. It can also show us whether the lunar surface is firm and hard enough to sustain a manned landing, or whether it is composed of loose dust. Thirdly, it will be able to determine whether or not the moon still has a hot, molten core, like the earth, or is a completely dead and inert body.

The instruments in Ranger's balsa ball are expected to keep operating and sending information back to earth for about a month. Then the power will go dead, but the ball will have done its job.

The second series of Rangers will have a different purpose. These craft will carry as many as six television cameras as well as instruments for measuring lunar radiation and dust patterns. The cameras will take thousands of pictures of the moon, in far greater detail than those of the first Ranger. When these pictures are shown on your home TV screen — as they probably will be — you will have the breath-taking experience of looking out of the nose of a rocket ship as it crashes on the moon.

If the balsa balls of the first Rangers have done their work well, no other moon landings will be necessary until the first Surveyor is launched.

The Surveyor-Lander vehicles, the next step after the Rangers, will be launched about two years later. These will be the first robots to make a con-

The Surveyor space craft with identification of its ingeniously designed components. Surveyor is planned to be landed in 1964.
trolled “soft” landing on the moon, just as manned spaceships will do.

Launched in much the same way as the Rangers, the Surveyor will be a far more complicated mechanism. When it comes to within landing distance of the moon, the Surveyor will be lowered gently to the lunar surface on the flaming jets of three powerful retrorockets. To understand how this is done, remember the pictures you have seen on TV of the launching of rockets from earth. In the beginning they ascend very slowly, sitting almost motionless for a few seconds on the flaming column of jet fire until they suddenly take off. The moon landings will simply reverse this process, allowing the Surveyor to ride the jets down instead of up.

Once it has landed safely, all of Surveyor’s marvelous instruments will go to work at once. Television cameras will scan the moonscape in every direction, taking pictures both in black-and-white and color. For the first time, watchers on earth will be able to determine the true lunar coloration.

Mechanical arms will reach out, pick up specimens of moon material, grind it up, analyze it, and report the findings. Drills will bore into the moon rock and submit it to analysis. Other devices will determine the hardness of the moon’s surface, and find out whether it is safe for a manned landing. Bombardment with X-rays will determine the extent to which the moon retains the hot gases that are thrown out by the sun.

A number of Surveyors will be landed on different parts of the moon so that scientists can decide which particular areas are best suited to later manned landings.

A second series of Surveyors will be known as Surveyor-Orbiters. Instead of landing, they will go into orbits around the moon in such a pattern as to cover, and photograph, the entire surface in a period of about a month. These photographs will be used to make detailed lunar maps and further determine the likeliest spots for later landings by humans.

After the Ranger and Surveyor vehicles have accomplished their missions, the next giant stride in the conquest and exploration of the
Project Apollo plans for a manned lunar landing in 1970.

Astronauts exploring the moon after landing of lunar bug. The giant globe over the moon-horizon is the earth.
moon will be to land a crew of human astronauts. As this book is being written, this project is still in the planning stage. It is believed that the first manned landing will not be possible until about 1969 or 1970. But already our scientists and our space crews are preparing for it. The program for finally landing men on the moon is called Project Apollo.

It is believed that the most feasible method of reaching the moon is by means of an Earth or Moon Orbit Rendezvous. Two spaceships will meet in an orbit around the moon or earth. One of them is a tanker, filled with rocket fuel. The second contains the crew that will make the moon voyage. After replenishing their rocket fuel from the tanker, the second ship then takes off for destination moon.

But before an actual moon trip can be launched, a great deal of crew training will be required. This training is already well under way. The training ship, a larger version of the one-man Mercury capsules that have already made several earth orbits, is a two-man craft known as Gemini. The chief mission of the Gemini crews will be to perfect the techniques of meeting with tankers while in orbit.

One distinguishing feature of the Gemini capsule is the fact that it will not parachute back to earth and land splashing in the sea as the Mercury capsules have done. Instead it will carry a collapsible "Rogallo wing" in its nose. This odd-looking combination of parachute and glider will inflate upon reentering the earth’s atmosphere and allow the astronauts to glide to a landing field.

After several Gemini crews have been trained, and the rendezvous techniques have been perfected, the astronauts will graduate to the larger Apollo spaceships. Apollo will carry three men, and will contain all the instruments and apparatus needed for an actual moon landing. This will include a small space cruiser officially known as the Lunar Excursion Vehicle, but more familiarly called the "bug.”

As the Apollo astronauts orbit the earth in practice flights, they will detach
the “bug” from the mother ship and take short space-rides in it. Then they will return in the “bug” to the Apollo craft before bringing it back to earth by means of the Rogallo wing.

Even with all the exploratory probes, and all their previous training, the astronauts will not be prepared to attempt an actual landing on the moon on their first lunar trip in Apollo. Instead, they will probably make one orbit of the moon, at a height of perhaps 100 miles. This orbit will give man his first opportunity to get a good, close-up, look at the lunar surface. The astronauts will observe the moon, compare its moonscape to the maps that will have been made with the help of the Surveyors, and further refine their selection of places on which they will eventually make a landing. They will then return to earth and land by means of the Rogallo wing.

On the second lunar voyage, it is planned that the Apollo will make a number of orbits around the moon, giving its crew an opportunity to take more pictures and spend several hours, or even days, studying the surface below them. They may even bring out the “bug” and fly it around the moon, to get the feel of how it handles when it is within the pull of the moon’s gravitational field.

On a flight through space, it will be possible for the astronauts to leave their ship whenever they wish to. Dressed in protective space-suits, they will be able to go outside into empty space to take their “bug” out of its storage space and put it in place for take-off, or to do any of a number of other tasks.
To get the necessary experience for future moon landings, one of the next steps to be carried out closer to the earth, might be the "rendezvous" of two spacecraft, orbiting the earth. Our illustration shows an artist's conception of such a joining of two vehicles, one astronaut "going calling on the other."

Repairs on the outside of the space ship or taking out of the bug will be done while the craft moves at full speed.

As the men are outside tending to these chores, the Apollo will be racing along at the incredible speed of something like 18,000 MPH. The astronauts will also be moving at this same rate. But in relation to the spacecraft, they will seem to be motionless. They will wear boots with magnetic soles to hold them fast to the metal sides of the ship. They will also be secured by short lifelines to keep them from drifting away into the endless sea of space.

To understand why the astronauts will feel no sensation of speed, think for a moment about the speed at which our own earth is moving. The ground
on which we stand, which seems so quiet and still on a pleasant summer afternoon, is actually spinning around at the furious rate of 1,000 miles an hour. The earth is racing around the sun at a speed of 66,000 miles an hour. And, along with the sun and all the planets, our earth is whizzing around the outside edge of the Milky Way at nearly half-a-million miles an hour, a speed almost impossible to imagine.

Yet, as we stand on earth, we feel completely motionless. That is the feeling which the astronauts will have as they clamber around the outside of their spaceships.
Then, if all has gone well, the first moon landing will be made. The Apollo, with its three-man crew, will go into a 100-mile-high orbit around the moon. Two of the crew will get into the “bug,” and put it into a much tighter orbit. At the perigee of the “bug’s” orbit, they will only be about ten miles above the moon’s surface. If they feel that everything is working perfectly, they will then make a landing much in the same way that the un-manned Surveyor did. They will ease to a touchdown riding four retrorocket jets of flame.

These first men on the moon will not stay long, perhaps only for an hour or two until the mother ship, Apollo, appears overhead. They will be asked to do no scientific tasks. Landing on the moon will be triumph enough. They will jettison their landing gear, fire their take-off rockets, and make rendezvous with the third man who was left in Apollo.

Thanks to the low lunar gravity, and the lack of atmosphere on the moon, taking off will be reasonably easy. They will probably abandon their “bug” which will continue to orbit the moon endlessly, and blast off for home. Back on earth they will find the greatest reception that any humans ever received from their fellow citizens.

This first exploratory landing will be followed by many others. From the first lunar visit of a few hours, successive teams of explorers will stay several days, or even several weeks.

The original team that lands on the moon may not stray more than a few tentative steps from their vehicle. But subsequent teams will go off on expeditions across the lunar surface. As man gets more accustomed to being on the moon, he will devise ways and means of moving about upon it. Some of these moon-machines are already in the design stages.

The lunar-tractors will employ many different ways to get around the rough and uncertain surface of the moon. Some of them will walk on spindly legs, in order to step over boulders and other obstructions that may lie in their paths. Others will roll along on ball-like wheels, so as to be able to pass over soft dust areas. Another will be simply a huge plastic ball that could bounce along over almost any kind of terrain.

As the first explorers encounter the
specific problems that moon travel entails, they will be able to determine which kind of vehicle is best suited to their needs. (See ill., p. 38.)

As we have seen, the moon will prove to be a very hostile and inhospitable place to live, even for a short while. Moon explorers, as they walk about the surface, will have to wear spacesuits that protect them from the moon’s lack of air, its absence of air pressure, its dangerous solar radiation, and its dangerous extremes of heat and cold.

The moon-suit will carry food, water, air conditioning equipment, and a two-way radio. The fact that it will weigh 200 pounds, which would make it almost impossible to wear on earth, will be no problem for the moon explorers, since it will only weigh one-sixth of that, or about 33 pounds, on the moon.

How will man survive on the moon?

To guard against the bombardment of meteorites that are constantly raining down on the moon, the first spacemen will probably dig, or blast, caves into the lunar rocks. Later, they will no doubt erect permanent shelters. These will be pressurized, so that humans can live and breathe in them just as the astronauts will be able to do in their spaceships.

Experimental models for such self-contained astrodomes are already in the preliminary test stages. Built of heavy plastic, the first of these are being tested under water in shallow parts of our
southern seacoast. If men can live and work in such structures at the bottom of the sea, engineers reason, it will be a relatively simple matter to modify them for conditions on the airless moon.

Another great problem will be that of supplies of food, water, and fuel. With today's rockets, it takes more than 100 pounds of rocket fuel to put one pound of payload into a moon trajectory. However, within the next decade, scientists are confident that these problems too will have been solved.

As we have seen, the many riddles of the moon are only just beginning to reveal themselves. You who read this are growing up in the first stages of the space age, and it will be well if you learn all that you can about our natural satellite.

Inexpensive telescopes can be readily purchased, or assembled from kits, that will enable you to observe the moon on clear nights in your own backyard. Several types of moon-maps are available for study. A large relief globe of the moon has recently been introduced, and is on sale at most bookstores and toy shops.

Even today, the moon is much closer to us than the New World was to Columbus. You can expect that by the time you are an adult, people will be making regular lunar voyages.

Who knows? Maybe one day you, yourself, may make a trip to the moon!
Produced and approved by noted authorities, these books answer the questions most often asked about science, nature and history. They are presented in a clear, readable style, and contain many colorful and instructive illustrations. Readers will want to explore each of these fascinating subjects and collect these volumes as an authentic, ready-reference, basic library.
